Section 9   Regression with Stationary Time Series

How time-series regression differs from cross-section

- Natural ordering of observations contains information
    - Random reshuffling of observations would obscure dynamic economic relationship, but leave traditional regression unchanged
    - How can we incorporate this dynamic information into our regression model?
- We usually think of the data as being drawn from a potentially infinite **data-generating process** rather than from a finite population of observations.
- Variables are often call "time series" or just "series" rather than variables
    - Index observations by time period t
    - Number of observations = T
- Dynamic relationship means that not all of the effects of x_t occur in period t.
    - A change in x_t is likely to affect y_{t+1}, y_{t+2}, etc.
    - By the same logic, y_t depends not only on x_t but also on x_{t-1}, x_{t-2}, etc.
    - We model these dynamic relationships with **distributed lag** models, in which $y_t = f\left(x_t, x_{t-1}, x_{t-2}, \ldots\right)$.
- We will need to focus on the dynamic elements of both the deterministic relationship between the variables and the stochastic relationship (error term)
- The dynamic ordering of observations means that the error terms are usually **serially correlated** (or autocorrelated over time)
    - Shocks to the regression are unlikely to completely disappear before the following period
        - Exception: stock market returns, where investors should respond to any shock and make sure that next period's return is not predictable
    - Two observations are likely to be more highly correlated if they are close to the same time than if they are more widely separated.
    - Covariance matrix of error term will have non-zero off-diagonal elements, with elements lying closest to the diagonal likely being substantially positive and decreasing as one moves away from the diagonal.
- **Nonstationary** time series create problems for econometrics.
    - We will study implications of and methods for dealing with nonstationarity in Section 12.
    - Example will illustrate nature of problem ("spurious regressions")
        - Regression of AL attendance on Botswana real GDP
        - Correlation = 0.9656

- $R^2 = 0.9323$
- Coefficient has t of 24.90.
- Good regression?

```

- o Correlation is spurious because both series are trending upward, so most of each series' deviation from mean is due to separate trends.
- o Much of the last 20 years in econometrics has been devoted to understanding how to deal with nonstationary time series.
- o We will study this intensively in a few weeks.
- o Nonstationarity forces us to remove the common trend (often by differencing) before interpreting the correlation or regression

Lag operators and differences

- With time-series data we are often interested in the relationship among variables at different points in time.
- Let x_t be the observation corresponding to time period t.
  - o The first lag of x is the preceding observation: x_{t-1}.
  - o We sometimes use the **lag operator** $L(x_t)$ or $Lx_t \equiv x_{t-1}$ to represent lags.
  - o We often use higher-order lags: $L^s x \equiv x_{t-s}$.
- The first difference of x is the difference between x and its lag:
  - o $\Delta x_t \equiv x_t - x_{t-1} = (1 - L)x_t$
  - o Higher-order differences are also used:
    $\Delta^2 x_t = \Delta(\Delta x_t) = (x_t - x_{t-1}) - (x_{t-1} - x_{t-2}) = x_t - 2x_{t-1} + x_{t-2}$
    $= (1 - L)^2 x_t = (1 - 2L + L^2)x_t$
  - o $\Delta^s x_t = (1 - L)^s x_t$
- Difference of the log of a variable is approximately equal to the variable's growth rate:
  $\Delta(\ln x_t) = \ln x_t - \ln x_{t-1} = \ln(x_t / x_{t-1}) \approx x_t / x_{t-1} - 1 = \Delta x_t / x_t$
  - o Log difference is exactly the continuously-compounded growth rate
  - o The discrete growth-rate formula $\Delta x_t / x_t$ is the formula for once-per-period compounded growth

- Lags and differences in Stata
  - First you must define the data to be time series: tsset year
    - This will correctly deal with missing years in the year variable.
    - Can define a variable for quarterly or monthly data and set format to print out appropriately.
    - For example, suppose your data have a variable called month and one called year. You want to combine into a single time variable called time.
      - gen time = ym(year, month)
      - This variable will have a %tm format and will print out like 2010m4 for April 2010.
      - You can then do tsset time
  - Once you have the time variable set, you can create lags with the lag operator l. and differences with d.
    - For example, last period's value of x is l.x
    - The change in x between now and last period is d.x
    - Higher-order lags and differences can be obtained with l3.x for third lag or d2.x for second difference.

Autocovariance and autocorrelation

- Autocovariance of order s is $\text{cov}(x_t, x_{t-s})$
  - We generally assume that the autocovariance depends only on s, not on t.
  - This is analogous to our Assumption #0: that all observations follow the same model (or were generated by the same data-generating process)
  - This is *one element* of a time series being stationary
- Autocorrelation of order s (ρ_s) is the correlation coefficient between x_t and x_{t-s}.
  - $\rho_k = \dfrac{\text{cov}(x_t, x_{t-k})}{\text{var}(x_t)}$

  - We estimate with $r_k = \dfrac{\dfrac{1}{T-k} \sum\limits_{t=k+1}^{T} (x_t - \bar{x})(x_{t-s} - \bar{x})}{\dfrac{1}{T} \sum\limits_{t=1}^{T} (x_t - \bar{x})}$.

    - We sometimes subtract one from both denominators, or sometimes ignore the different fractions in front of the summations since their ratio goes to 1 as T goes to ∞.
- ρ_k as a function of k is called the **autocorrelation function** of the series and its plot is often called a **correlogram**.

Some simple univariate time-series models

- We sometimes represent a variable's time-series behavior with a univariate model.

- **White noise:** The simplest univariate time-series process is called white noise $y_t = v_t$, where v_t is a mean-zero IID error (usually normal).
    - The key point here is the autocorrelations of white noise are all zero (except, of course, for ρ_0, which is always 1).
    - Very few economic time series are white noise.
        - Changes in stock prices are probably one.
    - We use white noise as a basic building block for more useful time series:
        - Consider problem of forecasting y_t conditional on all past values of y.
        - $y_t = E\left[y_t \mid y_{t-1}, y_{t-2}, \ldots\right] + v_t$
        - Since any part of the past behavior of y that would help to predict the current y should be accounted for in the expectation part, the error term v should be white noise.
        - The one-period-ahead forecast error of y should be white noise.
        - We sometimes call this forecast-error series the "fundamental underlying white noise series for y" or the "innovations" in y.
- The simplest autocorrelated series is the **first-order autoregressive (AR(1)) process**: $y_t = \beta_0 + \beta_1 y_{t-1} + v_t$, where e is white noise.
    - In this case, our one-period-ahead forecast is $E\left[y_t \mid y_{t-1}\right] = \beta_0 + \beta_1 y_{t-1}$ and the forecast error is v_t.
    - For simplicity, suppose that we have removed the mean from y so that $\beta_0 = 0$.
        - Consider the effect of a one-time shock v_1 on the series y from time one on, assuming (for simplicity) that $y_0 = 0$ and all subsequent v values are also zero.
        - $y_1 = \beta_1(0) + v_1 = v_1$
        - $y_2 = \beta_1 y_1 + v_2 = \beta_1 v_1$
        - $y_3 = \beta_1 y_2 + v_3 = \beta_1^2 v_1$
        - $y_s = \beta_1^{s-1} v_1$.
        - This shows that the effect of the shock on y "goes away" over time only if $|\beta_1| < 1$.
            - The condition $|\beta_1| < 1$ is necessary for the AR(1) process to be **stationary**.
        - If $\beta_1 = 1$, then shocks to y are permanent. This series is called a **random walk**.
            - The random walk process can be written $y_t = y_{t-1} + v_t$ or $\Delta y_t = v_t$. The first difference of a random walk is stationary and is white noise.
    - If y follows a stationary AR(1) process, then $\rho_1 = \beta_1$, $\rho_2 = \beta_1^2$, ..., $\rho_s = \beta_1^s$.

- One way to attempt to identify the appropriate specification for a time-series variable is to examine the autocorrelation function of the series.
- If the autocorrelation function declines exponentially toward zero, then the series might follow an AR(1) process with positive β_1.
- A series with $\beta_1 < 0$ would oscillate back and forth between positive and negative responses to a shock.
  - The autocorrelations would also oscillate between positive and negative while converging to zero.

Assumptions of time-series regression

- Before we deal with issues of specifications of y and x, we will think about the problems that serially correlated error terms cause for OLS regression. (GHL's Section 9.3)
- Can estimate time-series regressions by OLS as long as y and x are stationary and x is exogenous.
  - **Exogeneity**: $E\left(e_t \mid x_t, x_{t-1}, \ldots\right) = 0$.
  - **Strict exogeneity**: $E\left(e_t \mid \ldots, x_{t+2}, x_{t+1}, x_t, x_{t-1}, x_{t-2}, \ldots\right) = 0$.
- Assumptions of time-series regression:
  - **TSMR2:** y and x are stationary and x is strictly exogenous
  - **TSMR3:** $E\left(e_t\right) = 0$
  - **TSMR4:** $\operatorname{var}\left(e_t\right) = \sigma^2$
  - **TSMR5:** $\operatorname{cov}\left(e_t, e_s\right) = 0$, $t \neq s$
  - **TSMR6:** $e_t \sim N\left(0, \sigma^2\right)$
- However, nearly all time-series regressions are prone to having serially correlated error terms, which violates TSMR5.
  - Omitted variables are probably serially correlated
- This is a particular form of violation of the IID assumption.
  - Observations are correlated with those of nearby periods
- As long as the other OLS assumptions are satisfied, this causes a problem not unlike heteroskedasticity
  - OLS is still unbiased and consistent
  - OLS is not efficient
  - OLS estimators of standard errors are biased, so cannot use ordinary t statistics for inference
- To some extent, adding more lags of y and x to the specification can reduce the severity of serial correlation.
- Two methods of dealing with serial correlation of the error term:

- o GLS regression in which we transform the model to one whose error term is not serially correlated
  - ▪ This is analogous to weighted least squares (also a GLS procedure)
- o Estimate by OLS but use standard error estimates that are robust to serial correlation

Detecting autocorrelation

- o We can test the autocorrelations of a series to see if they are zero.
  - ▪ Asymptotically, $\sqrt{T}r_k \sim N(\rho_k, 1)$, so we can compute this as a test statistic and test against the null hypothesis $\rho_k = 0$.
- o **Breusch-Godfrey Lagrange multiplier test** for autocorrelation:
  - ▪ Regress y (or residuals) on x and lagged residuals (first-order, or more)
  - ▪ Use F test of residual coefficient(s) in y regression or TR^2 in residual regression as χ^2
- o **Box-Ljung Q test** for null hypothesis that the first k autocorrelations are zero:

$$Q_k = T(T+2)\sum_{j=1}^{k}\frac{r_j^2}{T-j} \text{ is asymptotically } \chi_k^2.$$

- o **Durbin-Watson test** used to be the standard test for first-order autocorrelation, but was difficult because critical values depend on x. Not used much anymore.

Estimation with autocorrelated errors

- OLS with autocorrelated errors
  - o Assumption TSMR4 is violated, which leads to inefficient estimators and biased standard errors just like in case of heteroskedasticity
  - o **Important special case:** We will see that a common distributed lag model puts y_{t-1} on the right-hand side as a regressor. This causes special problems when there is serial correlation because
    - ▪ e_{t-1} is part of y_{t-1}
    - ▪ e_{t-1} is correlated with e_t
    - ▪ Therefore e_t is correlated with one of the regressors, which leads to bias and inconsistency in the coefficient estimators.
    - ▪ If we can transform the model into one that has no autocorrelation (for example, v_t if error term is $e_t = \rho e_{t-1} + v_t$), then we can get consistent OLS estimators as long as all the x variables are exogenous (but not necessarily strictly exogenous) with respect to v.
- **HAC consistent standard errors** (Newey-West)
  - o As with White's heteroskedasticity consistent standard errors, we can correct the OLS standard errors for autocorrelation as well.

- We know that

$$b_2 = \beta_2 + \frac{\dfrac{1}{T}\sum_{i=1}^{T}(x_t - \bar{x})e_t}{\dfrac{1}{T}\sum_{i=1}^{T}(x_t - \bar{x})^2}.$$

- In this formula, $\operatorname{plim}\bar{x} = \mu_X$, $\operatorname{plim}\left(\dfrac{1}{T}\sum_{i=1}^{T}(x_t - \bar{x})^2\right) = \sigma_X^2$.

- So $\operatorname{plim}(b_2 - \beta_2) = \dfrac{\operatorname{plim}\left(\dfrac{1}{T}\sum_{i=1}^{T}(x_t - \mu_X)e_t\right)}{\sigma_X^2} = \dfrac{\operatorname{plim}(\bar{u})}{\sigma_X^2}$, where $\bar{u} = \dfrac{1}{T}\sum_{t=1}^{T}u_t$ and

  $u_t \equiv (X_t - \mu_X)e_t$.

- And in large samples, $\operatorname{var}(b_2) = \operatorname{var}\left(\dfrac{\bar{u}}{\sigma_X^2}\right) = \dfrac{\operatorname{var}(\bar{u})}{\sigma_X^4}$.

  - Under IID assumption, $\operatorname{var}(\bar{u}) = \dfrac{1}{T}\operatorname{var}(u_t) = \dfrac{\sigma_u^2}{T}$, and the formula reduces to one we know from before.
  - However, serial correlation means that the error terms are not IID (and x is usually not either), so this doesn't apply.

- In the case where there is serial correlation we have to take into account the covariance of the u_t terms:

$$\operatorname{var}(\bar{u}) = \operatorname{var}\left(\frac{u_1 + u_2 + \ldots + u_T}{T}\right)$$

$$= \frac{1}{T^2}\left[\sum_{i=1}^{T}\sum_{j=1}^{T}E(u_i u_j)\right]$$

$$= \frac{1}{T^2}\sum_{i=1}^{T}\left(\operatorname{var}(u_i) + \sum_{j\neq i}\operatorname{cov}(u_i, u_j)\right)$$

$$= \frac{1}{T^2}\left[T\operatorname{var}(u_t) + 2(T-1)\operatorname{cov}(u_t, u_{t-1}) + 2(T-2)\operatorname{cov}(u_t, u_{t-2}) + \ldots + 2\operatorname{cov}(u_t, u_{t-(T-1)})\right]$$

$$= \frac{\sigma_u^2}{T}f_T,$$

where

$$f_T \equiv 1 + 2\sum_{j=1}^{T-1}\left(\frac{T-j}{T}\right)\operatorname{corr}(u_t, u_{t-j})$$

$$= 1 + 2\sum_{j=1}^{T-1}\left(\frac{T-j}{T}\right)\rho_j.$$

- Thus, $\operatorname{var}(b_2) = \left[\dfrac{1}{T}\dfrac{\sigma_u^2}{\sigma_X^4}\right]f_T$, which expresses the variance as the product of the

  no-autocorrelation variance and the f_T factor that corrects for autocorrelation.

- o In order to implement this, we need to know f_T, which depends on the autocorrelations of u for orders 1 through $T-1$.
  - ▪ These are not known and must be estimated.
  - ▪ For ρ_1 we have lots of information because there are $T-1$ pairs of values for (u_t, u_{t-1}) in the sample.
  - ▪ For ρ_{T-1}, there is only one pair $(u_t, u_{t-(T-1)})$—namely (u_T, u_1)—on which to base an estimate.
  - ▪ The **Newey-West** procedure truncates the summation in f_T at some value $m-1$, so we estimate the first $m-1$ autocorrelations of v using the OLS residuals and compute $\hat{f}_T = 1 + 2\sum_{j=1}^{m-1}\left(\frac{m-j}{m}\right)r_j$.
  - ▪ m must be large enough to provide a reasonable correction but small enough relative to T to allow the r values to be estimated well.
    - • Stock and Watson suggest choosing $m = 0.75T^{\frac{1}{3}}$ as a reasonable rule of thumb.
- o To implement in Stata, use hac option in xtreg (with panel data) or post-estimation command newey , lags(m)
- • **GLS with an AR(1) error term**
  - o One of the oldest time-series models (and not used so much anymore) is the model in which e_t follows and AR(1) process:
    $$y_t = \beta_0 + \beta_1 x_t + e_t$$
    $$e_t = \rho e_{t-1} + v_t,$$
    where ε is a white-noise error term and $-1 < \rho < 1$.
    - ▪ In practice, $\rho > 0$ nearly always
  - o GLS transforms the model into one with an error term that is not serially correlated.
  - o Let
    $$\tilde{y}_t = \begin{cases} y_t\sqrt{(1-\rho^2)}, & t=1, \\ y_t - \rho y_{t-1}, & t=2,3,\ldots,T, \end{cases} \qquad \tilde{x}_t = \begin{cases} x_t\sqrt{(1-\rho^2)}, & t=1, \\ x_t - \rho x_{t-1}, & t=2,3,\ldots,T, \end{cases}$$
    $$\tilde{e}_t = \begin{cases} e_t\sqrt{(1-\rho^2)}, & t=1, \\ e_t - \rho e_{t-1}, & t=2,3,\ldots,T. \end{cases}$$
  - o Then $\tilde{y}_t = (1-\rho)\beta_1 + \beta_2\tilde{x}_t + \tilde{e}_t$.
    - ▪ The error term in this regression is equal to v_t for observations 2 through T and is a multiple of e_1 for the first observation.

- By assumption, v is white noise and values of v in periods after 1 are uncorrelated with e_1, so there is no serial correlation in this transformed model.
- If the other assumptions are satisfied, it can be estimated efficiently by OLS.
  - But what is ρ?
    - Need to estimate ρ to calculate feasible GLS estimator.
    - Traditional estimator for ρ is $\hat{\rho} = \text{corr}(\hat{e}_t, \hat{e}_{t-1})$ using OLS residuals.
    - This estimation can be iterated to get a new estimate of ρ based on the GLS estimator and then re-do the transformation: repeat until converged.
  - Two-step estimator using FGLS based on $\hat{\rho}$ is called the **Prais-Winsten** estimator (or **Cochrane-Orcutt** when first observation is dropped).
  - Problems: ρ is not estimated consistently if e_t is correlated with x_t, which will always be the case if there is a lagged dependent variable present and may be the case if x is not strongly exogenous.
    - In this case, we can use nonlinear methods to estimate ρ and β jointly by search.
    - This is called the **Hildreth-Lu** method.
  - In Stata, the prais command implements all of these methods (depending on option). Option corc does Cochrane-Orcutt; ssesearch does Hildreth-Lu; and the default is Prais-Winsten.
  - You can also estimate this model with ρ as the coefficient on y_{t-1} in an OLS model, with or without the restriction implied in HGL's equation (9.44).

Distributed-lag models

- Modeling the **deterministic part** of a dynamic relationship between two variables
- In general, the distributed-lag model has the form $y_t = \alpha + \sum_{i=0}^{\infty} \beta_i x_{t-i} + e_t$. But of course, we cannot estimate an infinite number of lag coefficients β_i, so we must either truncate or find another way to approximate an infinite lag structure.
  - **Multipliers**
    - $\dfrac{\partial E(y_t)}{\partial x_{t-s}} = \beta_s$ is the s-period delay multiplier, telling how much a one-time, temporary shock to x would be affecting y s periods later
    - β_0 is the "impact multiplier"

- $\sum_{r=0}^{s} \beta_r$ is the cumulative or "interim" multiplier after s periods. It measures the cumulative effect of a permanent change in x on y s periods later.

- $\sum_{s=1}^{\infty} \beta_s$ is the "total multiplier" measuring the final cumulative effect of a permanent change in x on y.

  o We can easily have additional regressors with either the same or different lag structures.

- **Finite distributed lags**
  o $y_t = \alpha + \beta_0 x_t + \beta_1 x_{t-1} + \ldots + \beta_q x_{t-q} + e_t = \alpha + \beta(L) x_t + e_t$
  o This is finite distributed-lag model of order q
  o Under assumptions TSMR1–6, the model can be estimated by OLS. If there is serial correlation, then the appropriate correction must be made to standard errors or a GLS model must be used.
  o Problems with finite DL model
    - If x is strongly autocorrelated, then collinearity will be a problem and it will be difficult to estimate individual lag weights accurately
    - Difficult to know appropriate lag length (can use AIC or SC)
    - If lags are long and sample is short, will lose lots of observations.

- **Koyck lag: y is AR(1) with regressors**
  o $y_t = \delta + \theta_1 y_{t-1} + \delta_0 x_t + v_t$
  o $\dfrac{\partial y_t}{\partial x_t} = \delta_0$

    $\dfrac{\partial y_{t+1}}{\partial x_t} = \theta_1 \delta_0$

    $\dfrac{\partial y_{t+2}}{\partial x_t} = \theta_1^2 \delta_0$

    $\dfrac{\partial y_{t+s}}{\partial x_t} = \theta_1^s \delta_0$

    Thus, dynamic multipliers start at δ_0 and decay exponentially to zero over infinite time. Thus, this is effectively a distributed lag of infinite length, but with only 2 parameters (plus intercept) to estimate.

  o Cumulative multipliers are $\sum_{k=0}^{s} \dfrac{\partial y_{t+k}}{\partial x_t} = \delta_0 \sum_{k=0}^{s} \theta_1^k$.

  o Long-run effect of a permanent change is $\delta_0 \sum_{k=0}^{\infty} \theta_1^k = \dfrac{\delta_0}{1 - \theta_1}$.

  o Estimation has the potential problem of inconsistency if v_t is serially correlated.

- This is a serious problem, especially as some of the test statistics for serial correlation of the error are biased when the lagged dependent variable is present.
    - o Koyck lag is parsimonious and fits lots of lagged relationships well.
    - o With multiple regressors, the Koyck lag applies the same lag structure (rate of decay) to all regressors.
        - Is this reasonable for your application?
        - Example: delayed adjustment of factor inputs: can't stop using expensive factor more quickly than you start using cheaper factor.
- **ARX(p) Model**
    - o We can generalize the Koyck lag model to longer lags:
    $$y_t = \delta + \theta_1 y_{t-1} + \ldots + \theta_p y_{t-p} + \delta_0 X_t + v_t.$$
    - o This can be written $\theta(L) y_t = \delta + \delta_0 x_t + v_t.$
    - o Same general principles apply:
        - Worry about stationarity of lag structure: roots of $\theta(L)$
        - If v is serially correlated, OLS will be biased and inconsistent
        - Dynamic multipliers are determined by coefficients of infinite lag polynomial $[\theta(L)]^{-1}$
        - If more than on x, all have same lag structure
    - o How to determine length of lag p?
        - Can keep adding lags as long as θ_p is statistically significant
        - Can choose to max the Akaike information criterion (AIC) or Bayesian (Schwartz) information criterion (SC).
        - Note that regression can use as many as $T - p$ observations, but should use the same number for all regressions with different p values in assessing information criteria.
        - AIC will choose longer lag than SC.
            - AIC came first, so is still used a lot
            - SC is asymptotically unbiased
        - Stata calculates info criteria by estat ic (after regression)
- **ADL(p, q) Model: "Rational" lag**
    - o We can also add lags to the x variable(s)
    - o $y_t = \delta_0 + \theta_1 y_{t-1} + \ldots + \theta_p y_{t-p} + \delta_0 x_t + \delta_1 x_{t-1} + \ldots + \delta_q x_{t-q} + v_t$
        - Can add more x variables with varying lag lengths
    $$\theta(L) y_t = \delta_0 + \delta(L) x_t + v_t,$$
    - o $y_t = \dfrac{\delta_0}{\theta(L)} + \dfrac{\delta(L)}{\theta(L)} x_t + \dfrac{v_t}{\theta(L)}.$

- Multipliers are the (infinite) coefficients on the lag polynomial $\dfrac{\delta(L)}{\theta(L)}$

- o Stationarity depends only on $\theta(L)$, not on $\delta(L)$.
- o Can easily estimate this by OLS assuming:
  - $E\left(v_t \mid y_{t-1}, y_{t-2}, \ldots, y_{t-p}, x_t, x_{t-1}, \ldots, x_{t-q}\right) = 0$
  - (y_t, x_t) has same mean, variance, and autocorrelations for all t
  - (y_t, x_t) and (y_{t-s}, x_{t-s}) become independent as $s \to \infty$
  - No perfect multicollinearity
- o These are general TSMR assumptions that apply to most time-series models.

Forecasting with time-series models

- **With AR(p) model**
  - o $y_t = \delta + \theta_1 y_{t-1} + \theta_2 y_{t-2} + \ldots + \theta_p y_{t-p} + v_t$, with v assumed to be serially uncorrelated.
  - o We have observations for $t = 1, 2, \ldots, T$
  - o Forecast for $T + 1$: $\hat{y}_{T+1} = \hat{\delta} + \hat{\theta}_1 y_T + \hat{\theta}_2 y_{T-1} + \ldots + \hat{\theta}_p y_{T-p+1}$ with expected value of v at zero because of no serial correlation
    - If error term were autoregressive, then conditional expectation of v_{T+1} would be ρv_T, so would include residual of observation T
  - o Forecast error is $u_1 = y_{T+1} - \hat{y}_{T+1} = \left(\delta - \hat{\delta}\right) + \sum_{s=1}^{p}\left(\theta_s - \hat{\theta}_s\right) y_{T+1-s} + v_{T+1}$
    - HGL assume that $\operatorname{var}\left(v_{T+1}\right) \gg \operatorname{var}\left[\left(\delta - \hat{\delta}\right) + \sum_{s=1}^{p}\left(\theta_s - \hat{\theta}_s\right) y_{T+1-s}\right]$, so they ignore the latter.
    - I'm not willing to ignore this (although it is often true that the variance of the error is larger, as in Problem 6.17.
    - I will write $e_{b,k} = \left(\delta - \hat{\delta}\right) + \sum_{s=1}^{p}\left(\theta_s - \hat{\theta}_s\right) y_{T+k-s}$ and $\operatorname{var}\left(e_{b,k}\right)$ to be that component of the k-period-ahead forecast and keep it in the equation
    - $u_1 = e_{b,1} + v_{T+1,}$
    - $\operatorname{var}\left(u_1\right) = \operatorname{var}\left(e_{b,1}\right) + \sigma_v^2$
  - o What about forecast for $T + 2$?
    - y_{T+1} appears on the right-hand side of the $T+2$ equation, so we substitute our one-period-ahead forecast of it:
    $$\hat{y}_{T+2} = \hat{\delta} + \hat{\theta}_1 \hat{y}_{T+1} + \hat{\theta}_2 y_T + \ldots + \hat{\theta}_p y_{T+2-p}$$

- Forecast error is

$$u_2 = y_{T+2} - \hat{y}_{T+2} = \left(\delta - \hat{\delta}\right) + \theta_1\left(\hat{y}_{T+1} - y_{T+1}\right) + \sum_{s=1}^{p}\left(\theta_s - \hat{\theta}_s\right)y_{T+2-s} + v_{T+2}$$

$$= e_{b,2} + \theta_1 e_{b,1} + v_{T+2} + \theta_1 v_{T+1}.$$

- Variance of forecast error is

$$\mathrm{var}\left(u_2\right) = \mathrm{var}\left(e_{b,2}\right) + \theta_1^2\,\mathrm{var}\left(e_{b,1}\right) + \left(1 + \theta_1^2\right)\sigma_v^2.$$

- Similarly,

$$\mathrm{var}\left(u_3\right) = \mathrm{var}\left(e_{b,3}\right) + \theta_1^2\,\mathrm{var}\left(e_{b,2}\right) + \left(\theta_1^2 + \theta_2\right)^2\,\mathrm{var}\left(e_{b,1}\right) + \left(1 + \theta_1^2 + \left(\theta_2 + \theta_1^2\right)^2\right)\sigma_v^2$$
